KEY MESSAGES

• For people with diabetes and end stage renal disease, kidney transplantation improves long-term outcomes compared with dialysis.
• For people with type 1 diabetes and end stage renal disease, simultaneous pancreas-kidney transplantation can improve kidney graft survival and result in prolonged insulin independence.
• For people with type 1 diabetes, pancreas or islet allotransplantation improves glycemic control, prevents severe hypoglycemia even in the absence of complete insulin independence, but with the risks of long-term immunosuppression.
• In people undergoing total pancreatectomy for benign pancreatic disease, islet autotransplantation can prevent or ameliorate labile diabetes.
• Post-transplant diabetes is common after solid organ transplantation and is associated with increased risk for mortality, cardiovascular disease and graft loss.

KEY MESSAGES FOR PEOPLE WITH DIABETES

• Diabetes sometimes damages kidneys so badly that they no longer work. When kidneys fail, one option is a kidney transplant.
• For certain people with type 1 diabetes, pancreas or islet transplants may help stabilize blood glucose levels.
• Your diabetes health-care team can discuss the benefits and risks of these procedures with you.

Introduction

Restoring endogenous insulin secretion by whole pancreas or islet transplantation has been established as an alternative to insulin injection therapy in select individuals with type 1 diabetes (1,2). Both pancreas and islet transplantation can result in insulin independence and glucose stability, especially in the setting of glucose lability or frequent, severe hypoglycemia. Unfortunately, the absence of prospective randomized controlled trials makes it challenging to draw firm conclusions about the overall efficacy and safety of these therapies compared with exogenous insulin treatment. Also, the limited number of specialized islet and pancreas transplantation centres and the relatively small number of donor pancreases limit the availability of these treatments.

More broadly, diabetes is an important clinical issue in solid organ transplantation. Diabetes is the leading indication for kidney transplants (3) and is a common comorbidity in people listed for other solid organ transplants. New cases of diabetes developing after solid organ transplantation—post-transplant diabetes mellitus (PTDM)—are common and associated with reduced patient and graft survival. There is uncertainty about many aspects of PTDM, including diagnostic criteria, screening, glycemic targets and which glucose-lowering therapies are safest and most effective after transplant (4). Nevertheless, some general recommendations regarding the role of pancreas and islet transplantation, and the diagnosis and management of PTDM, may be made based on a growing body of data and/or current clinical experience.

Pancreas Transplantation

Pancreas transplantation can result in complete independence from exogenous insulin in the majority of cases (5). As shown in Table 1, worldwide, non-controlled 1-, 5- and 10-year mean pancreas graft and patient survival rates differ slightly among the 3 major types of transplantations (6). Long-term pancreas graft survival declines with time, with a median graft survival of 9 years and <10% survival at 21 years (7). Chronic graft failure is the most common reason for transplant loss (8). Glycemic control and glycated hemoglobin (A1C) are markedly improved after successful pancreas transplantation, with most recipients achieving normal glucose tolerance, albeit with hyperinsulinemia (9,10). Improvements in the histological changes of diabetic nephropathy have been reported 5 to 10 years post-transplantation (11,12).

Long-term patient and kidney graft survival improves with simultaneous pancreas kidney (SPK) transplant (13–15). Improvement and/or stabilization of diabetic retinopathy has been demonstrated.

PAK, pancreas after kidney; PTA, pancreas transplant alone; SPK, simultaneous pancreas kidney.
Peripheral sensory and motor neuropathies also appear to improve after pancreas transplantation (17,18), but these findings are inconsistent and may take years to achieve (19–21). Pancreas transplantation appears to improve cardiovascular (CV) function, carotid intimal medial thickness, blood pressure (BP) and lipid parameters (22–24). Nonrandomized trials suggest a reduction in CV mortality (25,26). Finally, diabetes-related quality of life appears to improve after pancreas transplantation (27).

### Islet Transplantation

**Islet allotransplantation**

Islet allotransplantation involves the infusion of islets isolated from a deceased donor pancreas via the portal vein into the liver (28). Islet transplant alone in people with severe hypoglycemia and impaired awareness of hypoglycemia, despite optimal medical therapy, results in stable, near-normal glycemic control (A1C, glycemic variability) and protection from severe hypoglycemia (29). Similar benefits are seen for islet transplant simultaneously with, or after, kidney transplant compared with intensive insulin therapy (30). Islet transplant usually leads to insulin independence in most recipients, but often requires more than 1 islet infusion (31). Over time, long-term insulin independence rates decline, but recent studies suggest 5-year insulin independence rates up to 60% (32) compared with 10% in early reports (33). Higher proportions maintain long-term graft function, evidenced by sustained secretion of C-peptide, which facilitates improved glycemic control and protection from hypoglycemia despite resuming insulin therapy (29,34,35).

Small, studies suggest stabilization of microvascular complications (36) with islet allotransplantation. Also, successful islet transplantation can improve quality of life (37) and reduces the fear of hypoglycemia (38). Adverse effects of immunosuppressive agents, however, can have a negative impact on quality of life (39).

### Risks Associated with Pancreas and Islet Transplantation

Pancreas transplantation represents major abdominal surgery and is associated with significant perioperative risks, including graft thrombosis, hemorrhage, pancreatitis, wound infection, peripancreatic abscesses and duodenal stump leakage (40,41). Islet transplantation is a minimally invasive procedure and is associated with fewer procedural risks, which may include intraperitoneal hemorrhage or branch portal vein thrombosis, but these complications are infrequent at experienced centres (<10% of procedures) and usually self-limited (33,42). Both pancreas and islet transplantation require long-term immunosuppression, which is associated with a number of risks and side effects (43,44). Medication side effects are generally mild and often respond to dose or agent adjustment. Although rare, life-threatening opportunistic infections and malignancies have been reported (42,43). These risks must be carefully weighed against the potential benefits of transplantation for each individual. See Table 2 for a detailed comparison of pancreas vs. islet transplantation.

### Islet Autotransplantation after Pancreatectomy

Total pancreatectomy, most commonly performed for chronic painful pancreatitis, often results in labile, insulin-requiring diabetes with a high risk of hypoglycemia. Partial pancreatectomy (e.g. distal pancreatectomy for benign tumours) can also result in diabetes, albeit with a lower risk for hypoglycemia. In both total and partial pancreatectomy for benign pancreatic disease, islets can be isolated from the resected pancreas and returned to the person by infusion into the portal vein or the peritoneal cavity (45,46).

Islet autotransplantation does not require immunosuppression and has minimal additional operative risks. Islet autotransplantation after total pancreatectomy can prevent diabetes with no increase in mortality (47) and can result in durable insulin independence (48). Islet autotransplantation after partial pancreatectomy can also prevent diabetes and provides superior metabolic function, which may be particularly important in subjects at high risk for diabetes (49,50). The metabolic benefits of islet autotransplantation depend on the islet yield, which is generally lower than from deceased donors, but more than 50% of people undergoing total pancreatectomy will have meaningful glycemic benefit (51). Few centres in Canada have facilities to perform islet autotransplantation.

### Post-Transplant Diabetes Mellitus—Diagnosis and Treatment

Post-transplant diabetes mellitus (PTDM), previously known as new-onset diabetes after transplantation (NODAT), refers to newly diagnosed diabetes mellitus in a clinically stable person after solid organ transplantation (4). Transient hyperglycemia, which will generally have resolved within 3 months post-transplant is common.
and may require short-term treatment (4). Insulin is effective and may be the preferred agent in the acute setting or with marked hyperglycemia. A sensitive and practical method to screen for hyperglycemia in the initial 6-week post-transplant period in people taking corticosteroids is to measure capillary blood glucose (CBG) levels after lunch (i.e. 4 pm) (52).

PTDM is associated with reduced patient and graft survival and increased risk for CVD, infection and other complications of transplant (53). Risk factors for PTDM include recognized risk factors for type 2 diabetes (e.g. age, central obesity, metabolic syndrome, family history of type 2 diabetes), but also some specifically related to transplantation (hepatitis C, cytomegalovirus [CMV], corticosteroid dose, choice of immunosuppressive medications) (53). Pre-transplant screening can identify people at high risk for developing diabetes (54), but is not performed routinely in most transplant centres (4).

PTDM is diagnosed using standard glycemic thresholds (see Definition, Classification and Diagnosis of Diabetes, Prediabetes and Metabolic Syndrome chapter, p. S10) when clinically stable (i.e. not in the first 3 months post-transplant) (4). Although the 2-hour oral glucose tolerance test (OGTT) is a more sensitive diagnostic test than A1C, it may be less practical than other methods, but fasting plasma glucose (FPG) is the least sensitive test (55–57). After 3 months post-transplantation, A1C ≥6.5% can be used for diagnosis in stable organ transplant recipients (52,58).

Insulin is a common and effective antihyperglycemic therapy that is often initiated in hospital. While insulin has risks for both hyperglycemia and weight gain, it may be the preferred agent in the acute setting, particularly in the face of high-dose steroids with marked hyperglycemia (see In-Hospital Management of Diabetes chapter, p. S115).

To date, there have been no large trials of antihyperglycemic therapies for the treatment of PTDM. Some small studies have shown efficacy of dipeptidyl peptidase (DPP)-4 inhibitors (59,60) and less weight gain in a small trial vs. insulin glargine (61). However, there is not enough evidence to support specific recommendations regarding choice of antihyperglycemic therapy. Nevertheless, there are a number of issues, which may be considered when selecting glucose lowering therapies, similar to recommendations in the Pharmacologic Glycemic Management of Type 2 Diabetes in Adults chapter, p. S88.

Antihyperglycemic agents that do not promote weight gain would generally be preferred since steroids and weight gain are important risk factors for PTDM. Metformin would seem a sensible first-line agent, assuming adequate renal reserve and hepatic function. Adequate renal reserve would be required for a glucagon-like polypeptide (GLP)-1 receptor agonist or sodium-glucose cotransporter-2 (SGLT2) inhibitor to be considered. However, in immunosuppressed patients, the risks of genitourinary infection with SGLT2 inhibitors should be carefully considered (see Pharmacologic Glycemic Management of Type 2 Diabetes in Adults chapter, p. S88).

Insulin secretagogues have risks of hypoglycemia and weight gain, and have inferior durability (which is often attributed to accelerated progression of beta cell decline) (62). Avoiding use of insulin secretagogues in people at increased risk for hypoglycemia (transplant recipients with impaired hepatic or renal function) or in pancreas transplant recipients with graft dysfunction seems prudent.

Transplantation in People with Pre-Existing Diabetes

People with pre-existing diabetes often experience hyperglycemia following transplantation and may need additional anti-hyperglycemic therapy. Insulin may be required, at least temporarily. No controlled studies have examined treatment strategies for glycemic management after transplantation in people with pre-existing diabetes (4).

RECOMMENDATIONS

1. Individuals with type 1 diabetes and ESRD who are being considered for kidney transplantation should also be considered for simultaneous pancreas-kidney transplantation [Grade C, Level 2 (25,41)].

2. Individuals with type 1 diabetes with inadequate glycemic control characterized by marked glycemic lability and/or severe hypoglycemia despite best efforts to optimize glycemic control and who have a) preserved renal function or b) who have had a successful kidney transplant may be considered for islet allotransplantation [Grade C, Level 3 (29,30)] or pancreas transplantation [Grade C, Level 3 (26) for pancreas after kidney; Grade D, Level 4 (44) for pancreas transplant alone].

3. Individuals undergoing total pancreatectomy for benign pancreatic disease may be considered for islet autotransplantation to prevent the development of diabetes where suitable facilities are accessible [Grade D, Level 4 (47)].

4. Individuals undergoing solid organ transplant should be screened for diabetes and CV risk factors prior to transplant [Grade D, Consensus] and should be screened for PTDM after transplant using:
   a. A1C at 3 months, 12 months and then annually, or with an OGTT if A1C not reliable (see Table 1 in the Monitoring Glycemic Control chapter, p. S47) [Grade C, Level 3 (52,58)]
   b. A 2-hour OGTT or post-lunch capillary blood glucose in the first 3 months after transplant [Grade C, Level 3 (52)]

5. Individuals with PTDM should:
   a. Be treated to individualized glycemic targets [Grade D, Consensus]
   b. Receive healthy behaviour interventions similar to those recommended for people with type 2 diabetes [Grade D, Consensus]
   c. Receive antihyperglycemic agents that do not provoke weight gain, whenever possible, unless contraindicated [Grade D, Consensus]
   d. Avoid insulin secretagogues if they have renal impairment or poorly functioning pancreas transplant [Grade D, Consensus]
   e. Receive insulin for metabolic decompensation or symptomatic/severe hyperglycemia [Grade D, Consensus]
